

Fundamentals of wheel-road interaction

The design for the wheel construction

Conditions of wheel-tire interaction

- (a) Rigid wheel on hard terrain
- (b) Flexible/elastic wheel on hard terrain
- (c) Rigid wheel on deformable terrain
- (d) Flexible/elastic wheel on deformable terrain

Freebody Diagram

w = weight
 F_x = resistance to motion / Rolling resistance
 F_y = Force that pushes or pulls the wheel along

Sum of all forces and moments should be zero

Forces on ground/drive shaft

Forces on frame/drive shaft

Traction

Frictional force that allows wheel to grip the surface by moving or preventing it from slipping. In context of wheeled locomotion, friction is dry friction. It is caused by interaction of surface micro-features. It is part adhesion and part asperity.

Mechanical friction

Friction that results by interaction of contact between two surfaces that are not moving relative to each other. Occurs when an object is stationary and you try to move it. Asperity (roughness) with the force applied up to a certain level.

$$F_{max} \leq \mu_s W$$

Static friction

Force that opposes the motion of two surfaces sliding past each other once they are already moving. Acts when object is in motion. Asperity is usually lower than static friction.

$$F_{max} = \mu_k W$$

Fluidity of friction

- Independent of shape and size of contact area
- Depends on type of materials in contact
- Independent of history of contact

Rolling resistance

The resistance to motion caused by:

- **Hysteresis in material**
 happens because the material of wheel deforms as it moves in contact with ground and then returns to its shape after leaving contact, when wheel deforms, energy is absorbed by the material, but not all of this energy is returned back - This energy loss causes resistance. When the wheel moves forward, new portions of the tire deform, and previous portions return, causing a continuous cycle of energy loss.
- **Sliding losses**
 When through the shape geometry only, there is often a small amount of slipping or sliding between the tire and the surface particularly at the contact point where the tire leaves the ground. This (sliding contact) friction, which leads to energy being converted into heat, further increasing rolling resistance.
- **Air resistance**
 Air trapped inside may come around as the tire deforms and rolls. This resistance of air inside the tire can create internal friction, leading to additional energy losses and, consequently, higher rolling resistance.
- Affected by type of material, tire design, speed, inflation pressure, operational conditions

$$F_r = f_r W$$

f_r = rolling resistance coefficient

$$\text{car tires: } f_r = 0.0075C + 0.014v^2 + 0.0001v^3$$

$$\text{truck tires: } f_r = 0.004C + 0.014v^2 + 0.0001v^3$$

Fundamentals of wheel-road interaction

- The wheel sinks into the soil and compresses and displaces the soil mass in front and under it.
- As the soil tries to resist, the resistance of the wheel, it experiences stresses (forces over area) and
- Occurs parallel to wheel-road interface, traction forces in soil mass
- Resistance depends on slip, loading, wheel/track geometry
- Energy is expended in compressing and displacing the soil

Normal stress - relates to ground pressure and weight

$$\sigma = \frac{W}{A}$$

Shear stress - relates to traction, slip, and dist

$$\tau = \frac{F}{A}$$

Ground pressure - ratio of contact patch

$$\sigma = \frac{W}{A} \text{ contact patch}$$

b = width of contact patch
 c = length of contact patch

where $\xi = \frac{b}{c}$

Condition for soil to fail

A Mohr-Coulomb failure criterion: Material will fail if the shear stress at a point exceeds the following condition:

$$\tau < c + \sigma \tan \phi$$

τ = shear stress
 c = cohesion
 σ = normal stress due to compression
 ϕ = soil angle of internal friction

Cohesion: relates to the shear strength that holds together soil particles (other than friction) and is independent of normal pressure.

Internal friction angle / angle of internal resistance to shearing: angle at which the material will slip on its own surface

Soil Thrust (S) / Tractive

How normal stress varies that the soil will sustain before failing (slipping) = soil tractive resistance

$$c = c + \sigma \tan \phi$$

$$cR = cR + \sigma R \tan \phi$$

$$M = cR + W \tan \phi$$

soil thrust is limited by wheel slip

$$M = \left[\frac{cR + W \tan \phi}{\xi} \right] \xi$$

soil thrust provides traction

Roller resistance due to soil compression

In deformable terrain, the wheel will sink into the ground, and the soil will resist. The resistance to motion (caused by R) is a result of this compression. We can model this roller resistance by integrating the pressure distribution over the contact area between the wheel and the soil.

$$R_c = \int \sigma dx db$$

R_c = roller resistance due to soil compression
 b = width of wheel
 σ = pressure of depth x in soil
 dx = depth of soil layer

Bulker's pressure-sinkage semi-empirical equation

$$p(x) = k \xi^2$$

k = soil parameters
 ξ = sinkage

cohesion coefficient

$$p_c = \left(\frac{2}{\xi} + k_1 \right) c \xi^2 \text{ sinkage dependent}$$

ϕ = angle of internal friction coefficient

$$R_c = b \int dx \left[\frac{2}{\xi} + k_1 \right] \left(\frac{2}{\xi} + k_1 \right) \xi^2 dx$$

For flexible wheel:

$$R_c = \left(\frac{2}{\xi} + k_1 \right) b \xi$$

For rigid wheel:

$$R_c = \left[\frac{2W}{(1 + \mu) \xi + k_1 b} \right] \xi^2$$

Elastic wheel:

$$R_{c,elastic} = \frac{W^2}{(b + \mu W) \xi^2}$$

Rigid wheel:

$$R_{c,rigid} = \frac{(2W)^2}{(1 + \mu) \xi + k_1 b}$$

Air Drag resistance due to rolling

Analytical expression of backdriving resistance (reference only)

Modeling using soil bearing capacity analysis:

$$R_c = \frac{W}{b} \left[\frac{2}{\xi} + k_1 \right] \xi^2$$

$$R_c = \frac{W}{b} \left[\frac{2}{\xi} + k_1 \right] \xi^2$$

Soil bearing capacity analysis:

- k_1 = soil parameters
- ξ = sinkage
- W = wheel weight
- b = wheel width
- μ = friction coefficient
- c = cohesion coefficient
- ϕ = angle of internal friction
- k_2 = roller resistance coefficient

Incompressible Soil

Assume horizontal rolling force that a vehicle can exert at the traction connection point where the vehicle rolls on (ground or track) with maximum forward motion. It is a measure of the soil's soil tractive resistance after equilibrium is reached and before the soil fails in shear.

$$DP = W \tan \phi$$

soil tractive resistance ξ_{max}

$$\xi_{max} = \frac{DP}{k_1}$$

soil(R) = R compression + R bulking + R penetration + R adhesion + R rolling + R internal

resistance due to engagement with ground material

Drive Torque of wheel output to overcome motion resistance

$$T_k = \sum R_c r$$

r = rolling radius of wheel
 ω = angular velocity of wheel

Drive power of wheel output to overcome motion resistance

$$P_k = \sum R_c v = \sum R_c \omega r$$

EXAMPLES

Summary of important equations for mobility in granular materials

Soil tractive resistance $R_c = \frac{W}{b} \left[\frac{2}{\xi} + k_1 \right] \xi^2$

Motion Resistance $\sum R_c = \sum R_{c,elastic} + \sum R_{c,rigid} + \sum R_{c,drag}$

Soil Thrust $M = (cR + W \tan \phi) \xi$ (soil resistance)

Drawbar Pull $DP = M - \sum R_c$

Drive Torque & Power (at motor output) $T_k = \sum R_c r, P_k = \sum R_c v$

Keynote for Evaluation

Mean Resistance Pressure (MRP)

$$\sigma_{MRP} = \frac{W}{\mu b \xi} \left[\frac{2}{\xi} + k_1 \right] \xi^2$$

mean(MRP) The average peak pressure exerted on a surface (such as soil or pavement) by a load

MRP is given vehicle weight (W)
 μ = number of wheels per axle
 b = average wheel track width (m)
 ξ = average sinkage (m) (see dimension L)
 k_1 = average soil deformation (see much the tire compresses under load) (m)
 n = total number of axles

Higher pressures can lead to more significant soil compaction and deeper sinkage, which impairs vehicle mobility.

Vehicle Ground Index (VGI)

Reflects degree of traction and traction admissibility for a given vehicle on a given soil

VGI is the dimensionless value of soil strength at which a vehicle can successfully negotiate one pass, given that the vehicle is moving on level ground at a slow steady speed and not pushing or towing

VGI as a function of the Mobility Index (MI)

The VGI is computed from the Mobility Index and a wheel deflection factor DCF:

$$VGI = 0.001 + 0.0001 MI + 0.0001 DCF$$

$$DCF = \frac{W}{\mu b \xi}$$

How to compute the Mobility Index (MI)

$$MI = \left(\frac{CFP}{RGP} \right) \left(\frac{DP}{RGP} \right) + LP - CF \left(\frac{DP}{RGP} \right) \left(\frac{DP}{RGP} \right)$$

- CFP: Contact Pressure Factor
- W: Weight Factor
- TP: Traction Element Factor (TP = 100)
- GF: Ground Factor
- LP: Load Factor (related to track)
- DP: Drawbar Pull
- RF: Resistance Factor
- TP: Traction Element Factor

Analysis and empirical data are used to calculate the vehicle before wheel compressions through MRP

MI Relates to critical configuration parameters

$$MI = \left(\frac{CFP}{RGP} \right) \left(\frac{DP}{RGP} \right) + LP - CF \left(\frac{DP}{RGP} \right) \left(\frac{DP}{RGP} \right)$$

- CFP = $\frac{W}{\mu b \xi}$
- W = Actual wheel weight (kg)
- μ = Actual axles (m)
- b = Rolling radius (m)
- ξ = Number of driven wheels
- RGP = $\frac{W}{\mu b \xi}$
- DP = Drawbar Pull
- LP = $\frac{W}{\mu b \xi}$
- CF = Number of driven axles
